

Summary of Results

We compare the differences in parameter optimization for different time lengths using Shirley Ma's data (folder 100714 Animal cap x0.8 Scion x2.0).

In the figures below, the blue dotted curves are the experimental edges and the red solid lines are the edges simulated from the model. The optimal parameters using the Full length of the movies (all 120 frames), First Half of the movies (frames 1-60), and Second Half of the movies (frames 61-120) are recorded for four explants of differing sizes.

Simulations of the Full length, First Half length, and Second Half length are run using the three sets of parameters. As expected, the parameters optimized for the time length in question result in the smallest least squares error comparing the experimental and simulated densities and edges.

For parameter ratio F/k , the value for the Full time length is the largest for all simulations. The First Half is the next largest for all simulations except Pos10 exp2.

For parameter ratio k/b , the value for the Second Half time length is the largest for all simulations, then the First Half time length, then the Full time length.

Assuming stretching modulus k is fixed, this means that lamellipodia force F and adhesion constant b is largest when simulating the Full time length. Comparing the First and Second Half time lengths, adhesion constant b is larger in the First Half and lamellipodia force F is generally larger in the First Half.

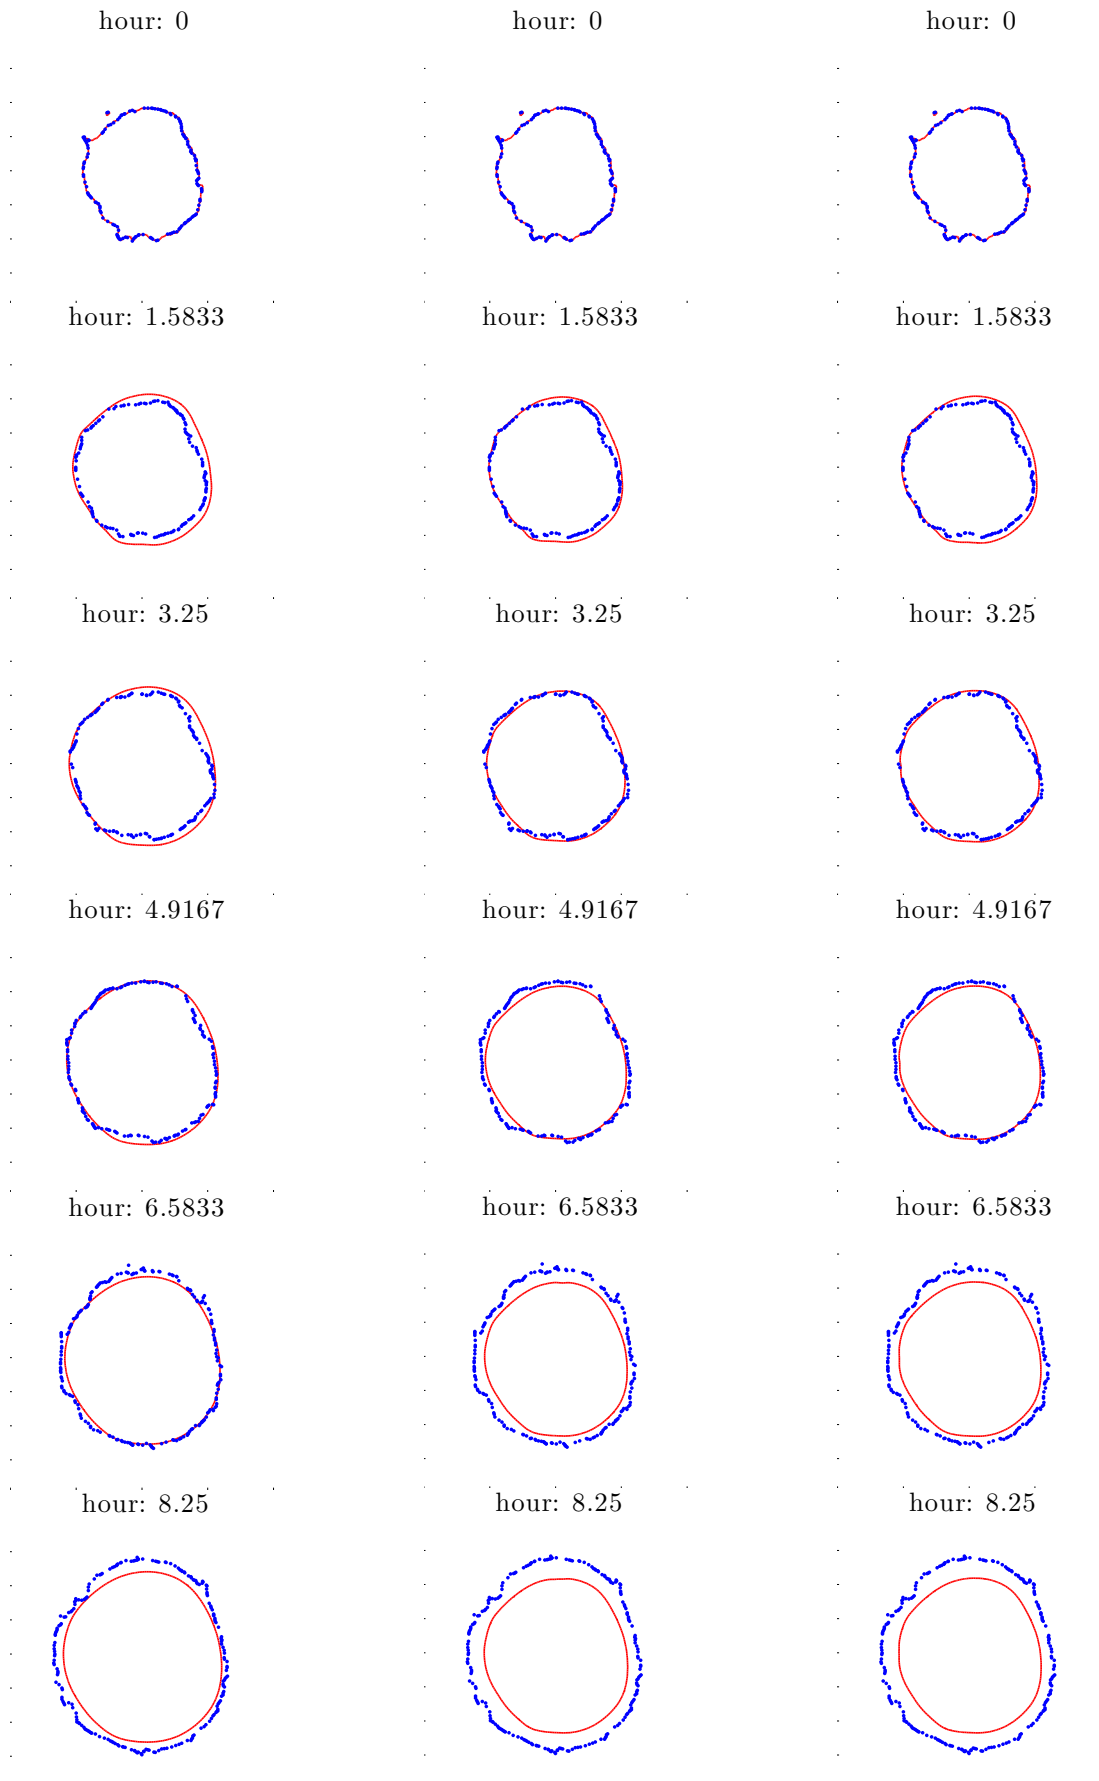

Also, adding the errors from the First Half (with parameters optimized for the First Half) and Second Half (with parameters optimized for the Second Half) is smaller than the error from the Full time length (with parameters optimized for the Full time length) for every simulation.

This might imply that the lamellipodia force and adhesion decreases over time in an explant of any size. It is unclear from this test whether there are distinct time periods where the parameters are relatively constant or if the parameters change continuously over time.
